Abstract

To make the development of efficient multi-core applications easier, libraries, such as Grand Central Dispatch, have been proposed. When using such a library, the programmer writes so-called blocks, which are chunks of codes, and dispatches them, using synchronous or asynchronous calls, to several types of waiting queues. A scheduler is then responsible for dispatching those blocks on the available cores. Blocks can synchronize via a global memory. In this paper, we propose Queue-Dispatch Asynchronous Systems as a mathematical model that faithfully formalizes the synchronization mechanisms and the behavior of the scheduler in those systems. We study in detail their relationships to classical formalisms such as pushdown systems, Petri nets, fifo systems, and counter systems. Our main technical contributions are precise worst-case complexity results for the Parikh coverability problem for several subclasses of our model.

1 Introduction

Over the last decades, the computing power delivered by processors has followed an exponential growing rate, mainly because of a steady increase in the CPU clock rates. Nowadays, however, further increasing the clock rates of CPUs incurs major engineering challenges, and multi-core CPUs have been introduced as an alternative way to achieve more computing power. The introduction of multicore CPUs, however, yields a major paradigm shift for programmers, as they must now write applications with parallelism in mind, in order to take advantage of those new platforms. Unfortunately, writing correct and efficient parallel code is a notoriously difficult task. The actual behaviour of a parallel program stems from the intricate interaction of the threads that run concurrently, and is thus hard to predict, hard to understand, hard to test, and hard to reproduce for debugging. Moreover, some parameters that can have a major influence on the efficiency of the code (such as the number of available cores, or the energy management policy of the platform) are usually known at runtime only. Thus, automatic tools to reason about such parallel applications running on multi-core platforms (and, in particular, to verify them) are sorely needed.
In order to help the programmer exploiting parallelism, several high level programming interfaces have been made available. A popular example is Grand Central Dispatch, GCD for short, a technology that is present in Mac OS X (since 10.6), iOS (since version 4), and FreeBSD. In GCD, the programmer writes so-called blocks which are chunks of codes, and dispatches them to waiting queues, together with several dependency constraints between those blocks (for instance, one block cannot start before the previous one in the queue has finished). The scheduler is then responsible for scheduling those blocks on the available cores, taking into account the current state of the computing platform (number of available cores, and so forth).

So far, to the best of our knowledge, no formal model has been proposed for systems relying on GCD or similar technologies, making those programs de facto out of reach of current verification methods and tools. This is particularly unfortunate as the control structure of such programs is very rich. For instance, as it is possible to dispatch an unbounded number of blocks to the queues, the state space of such programs is infinite even when the types of the variables are abstracted to finite domains.

Contributions In this paper, we introduce Queue-Dispatch Asynchronous Systems, QDAS for short, as a formal model for programs written using libraries such as GCD. Our model is composed of blocks (finite transition systems with finite data-domain variables) that can do asynchronous (non-blocking) and synchronous (blocking) calls to other blocks (recursion is allowed1). However, a call does not immediately trigger the execution of the callee: the block is inserted into a fifo queue that can be either concurrent or serial. In concurrent queues, several blocks can be taken from the queue and executed in parallel, while in serial queues, a block can be dequeued only if the previous block in the queue has completed its execution.

In the following, we formalize the verification question for QDAS through the Parikh coverability problem. The Parikh image of a QDAS configuration is a counting abstraction of the configuration that counts how many blocks are in each possible control state, see for example [11]. The Parikh coverability problem then asks whether the QDAS can reach a configuration c whose Parikh image covers a given Parikh image c′, i.e. whether there are, in c, at least as many blocks as in c′ in each control state. It is well-known that meaningful verification problems, such as mutual exclusion (‘are there at least two block in a critical section at the same time?’) can be reduced to this problem.

It is well-known that fifo systems, which are finite automata extended by a single unbounded fifo queue, can simulate a Turing machine. Thus one could expect that all non trivial decision problems (in particular, Parikh coverability) on QDAS with at least one (unbounded) queue will be undecidable, independent of the type of queue. While the Parikh coverability is, on the general QDAS model, undecidable, we show in this paper that some natural restrictions of the model enjoy decidability results even while retaining unbounded fifo queues. Intuitively, this rather surprising result stems

---

1As the reader will note later, classical (blocking) procedure calls (and so recursion) can be naturally coded in our model by synchronous calls to blocks. We could have added function calls (and so recursion) explicitly into the syntax of our model however at the cost of an additional unnecessary complexity to our definitions (and without any gain in term of expressiveness).
Table 1: Summary of Results, where \( \dag \) means “undecidable” from the fact that, in QDAS, queues contain blocks and not messages as in fifo systems. Moreover, running blocks cannot precisely control the dequeueing, as this is the responsibility of the scheduler. This prevents some non-trivial and meaningful classes of QDAS from simulating precisely fifo systems and allows to regain decidability.

More precisely, we show that QDAS with only synchronous calls are essentially equivalent to pushdown systems with finite domain data-variables, and we show that the Parikh coverability problem is \( \text{E}^{\text{XP}} \text{TIME}-\text{C} \) for that class (Theorem 1). Second, for synchronous QDAS with only serial queues, the problem is \( \text{PSPACE}-\text{C} \) (Theorem 2). Third, we show that QDAS with only asynchronous calls and only concurrent queues are essentially equivalent to lossy Petri nets and show that the Parikh coverability problem is \( \text{EXPSPACE}-\text{C} \) for that class (Theorem 3). This decidability border is precise as we show that if we allow either (i) asynchronous calls with synchronous queues, or (ii) synchronous and asynchronous calls with concurrent queues, then the Parikh coverability problem becomes undecidable (Theorem 4 and Theorem 5).

Remark: Due to the lack of space, detailed formal proofs are deferred to the appendix.

Related Works  The basic model-checking result for asynchronous programs is the \( \text{EXPSPACE}-\text{-hardness} \) for the control-state reachability problem obtained by making formal a link with multi-set pushdown systems (MPDS) \( \{14, 8, 12\} \). These programs however only allow to store pending asynchronous calls in (a set of) multisets and to execute one task per multiset. The close relation between asynchronous programs and Petri nets can also be used to prove additional decidability results \( \{10, 9\} \). Multi-set pushdown automata are subsumed by well-structured transition systems with auxiliary storage and inherit their decidability results presented in \( \{6, 7\} \). A series of parallel programming libraries and techniques is formalized in \( \{3\} \) with the help of recursively parallel programs. These allow to model fork/join based parallel computations based on a reduction to recursive vector addition systems with states. Recursively parallel programs only cover the classical asynchronous models presented above and not the advanced scheduling strategies for different queues that are part of our QDAS.

2 Preliminaries

Grand Central Dispatch (GCD) is a technology developed by Apple \( \{1, 2\} \) that is publicly available at [http://libdispatch.macosforge.org/](http://libdispatch.macosforge.org/) under a free license. GCD is the main inspiration for the formal model of queue-dispatch asynchronous systems. In the following, we often present our examples as pseudo code using a syntax inspired by GCD. In the GCD framework, the programmer has to split
his code into blocks. During the execution of a GCD program, one or several tasks run in parallel, each executing a given block (initially, only the main block is running). Tasks can call (or dispatch in the GCD vocabulary) other blocks, either synchronously (the call is blocking), or asynchronously (the call is not blocking). A dispatch consists in inserting the block into a fifo queue. In our examples, we use the keywords dispatch_a and dispatch_s to refer to asynchronous and synchronous dispatches respectively. At any time, the scheduler can decide to dequeue blocks from the queues and to assign them to tasks for execution. All queues ensure that the blocks are dequeued in FIFO order, however the actual scheduling policy depends on the type of queue. GCD supports two types of queues: concurrent queues allow several tasks from the same queue to run in parallel, whereas serial queues guarantee that at most one task is running per queue. In our examples, concurrent (resp. serial) queues are declared as global variables of type c_queue (s_queue). In addition, all blocks have access to the same set of global variables (in this work, we assume that the variables range over finite domains).

**Example 1** Let us consider the pseudo code in Fig. 1 that computes the product of two integer matrices matrix1 and matrix2 in a matrix matrix. The main task forks a series of one_cell blocks. Each one_cell computes the value of a single cell of the result. The parallelism is achieved via the GCD scheduler, thanks to asynchronous dispatches on the concurrent queue workqueue. Asynchronous dispatches ensure that main is not blocked after each dispatch, and a concurrent queue allow all the one_cell blocks to run in parallel. The variable count is incremented each time the computation of a cell is finished and acts as a semaphore for the main block, to ensure that matrix contains the completed result when main terminates. As only reading and writing to a variable are atomic, we need to guarantee exclusive access to count (line 7). This is achieved by a dedicated block increase that is dispatched to the serial queue semaphore. As only increase blocks can increase count, this queue implicitly locks the access to the variable.
Basic Notations: Given a set \( S \), let \(|S|\) denote its cardinality. For an \( I \)-indexed family of sets \((S_i)_{i \in I}\), we write elements of \( \prod_{i \in I} S_i \) in bold face, i.e., \( s \in \prod_{i \in I} S_i \). The \( i \)-component of \( s \) is written \( s_i \in S_i \), and we identify \( s \) with the indexed family of elements \((s_i)_{i \in I}\). We use \( \cup \) to denote the disjoint union of sets. An alphabet \( \Sigma \) is a finite set of letters. We write \( \Sigma^* \) for the set of all finite words, over \( \Sigma \) and denote the empty word by \( \varepsilon \). The concatenation of two words \( w, w' \) is represented by \( w \cdot w' \). For a letter \( \sigma \in \Sigma \) and a word \( w \in \Sigma^* \), let \(|w|_\sigma\) be the number of occurrences of \( \sigma \) in \( w \). We use standard complexity classes, e.g., polynomial time (PTIME) or deterministic exponential time (EXP\(\text{TIME}\)), and mark completeness by appending "\(-C\)" (e.g. PSPACE-C).

A labeled transition system (LTS) is a tuple \( TS = (S, s^0, \Sigma, \Rightarrow) \) where \( S \) is a set of states (sometimes called configurations), \( s^0 \in S \) is the initial state, \( \Sigma \) is an alphabet of actions, and \( \Rightarrow \subseteq S \times \Sigma \times S \) is a (labeled) transition relation. We usually write \( s \xrightarrow{a} s' \) in place of \((s, a, s') \in \Rightarrow\). A run \( p \) of \( TS \) is a finite alternating sequence \( s_0a_1s_1a_2 \ldots a_n s_n \) of configurations and actions where \((s_i, a_{i+1}, s_{i+1}) \in \Rightarrow\) for all \( 0 \leq i < n \) and \( s_0 = s^0 \). A configuration \( s \) is reachable in \( TS \) iff there exists a run \( s_0a_1s_1a_2 \ldots a_n s_n \) of \( A \) such that \( s_n = s \). We denote by \( \text{Reach}(TS) \) the set of all reachable configurations of \( S \). Given an LTS \( TS \) and a corresponding state \( s \), the LTS reachability problem asks whether \( s \in \text{Reach}(TS) \).

A pushdown system (PDS) is a tuple \( (X, x^0, \Phi, \Sigma, \Delta) \) where \( X \) is a finite set of (control) states, \( x^0 \in X \) is the initial state, \( \Phi \) is the stack alphabet and \( \Delta \subseteq X \times \Sigma \times X \) is the set of transitions with \( \Sigma = (\{\text{push, pop}\} \times \Phi) \cup \{\varepsilon\} \). The semantics of a pushdown system is given as infinite transition system over configurations \( S = X \times \Phi^* \) where the stack content is represented by a word in \( \Phi^* \) that is accessed in lifo manner. It is folklore, that a pushdown system with an additional action empty? \( \in \Sigma \), that can only be fired if the stack is empty, can be (linearly) reduced to one without. The reachability question for PDS is PTIME-C \( \mathbb{4} \).

Let \( \mathbb{D} \) be a finite data domain with an initial element \( d_0 \in \mathbb{D} \), and let \( \mathcal{X} \) be a finite set of variables ranging over \( \mathbb{D} \). A valuation of the variables in \( \mathcal{X} \) is a function \( d : \mathcal{X} \rightarrow \mathbb{D} \). An atom is an expression of the form \( x = d \) or \( x \neq d \), where \( x \in \mathcal{X} \) and \( d \in \mathbb{D} \). A guard is a finite conjunction of atoms. An assignment is an expression of the form \( x \leftarrow v \), where \( x \in \mathcal{X} \) and \( v \in \mathbb{D} \). Let guards (\( \mathcal{X} \)), assign (\( \mathcal{X} \)) and val (\( \mathcal{X} \)) denote respectively the sets of all guards, assignments and valuations over variables from \( \mathcal{X} \). Guards, atoms and valuations have their usual semantics: for all valuations \( d \) of \( \mathcal{X} \) and all \( g \in \text{guards}(\mathcal{X}) \), we write \( d \models g \) iff \( d \) satisfies \( g \).

A pushdown system with data is a pushdown system equipped with a finite set of variables \( \mathcal{X} \) over a finite domain \( \mathbb{D} \). A configuration of a PDS with data is a pair \((s, w, d)\) where \( s \) is a control state, \( w \) is the stack content, and \( d \) is a valuation of the variables

**Proposition 1** The reachability problem is EXP\(\text{TIME}\)-C for PDS with data.

A Petri net (PN) is a tuple \( N = (P,T,m_0) \) where \( P \) is a finite set of places, a marking of the places is function \( m : P \rightarrow \mathbb{N} \) that associates, to each place \( p \in P \) a number \( m(p) \) of tokens, \( T \) is a finite set of transitions, each transition \( t \in T \) is a pair \((I_t,O_t)\)
Figure 2: CTG for a QDAS with a concurrent queue $q_1$ and a serial queue $q_2$

where $I_t : P \rightarrow \{0,1\}$ and $O_t : P \rightarrow \{0,1\}$ are respectively the input and output functions of $t$, and $m_0$ is the initial marking. The preorder $\preceq$ compares markings: $m \preceq m'$ iff $m(p) \leq m'(p)$ for all $p \in P$. As usual, a transition $t$ is enabled in a marking $m$ if $I(t) \preceq m$. When fired from $m$, $t$ consumes one token in each input place and produces one token in the output places defining a new marking $m'$. This semantics can be formalized using an infinite transition system with set of configurations $\mathbb{N}^P$. A run in this transition system is a finite sequence $m_0 m_1 \ldots m_n$ s.t. for all $1 \leq i \leq n$: $m_{i-1} \rightarrow m_i$. For a PN $N$, we denote by Reach($N$) (resp. Cover($N$)) the reachability (coverability) set of $N$, i.e. the set of all markings $m$ s.t. there exists a run $m_0 m_1 \ldots m_n$ of $N$ with $m = m_n (m_0 \preceq m)$. The coverability problem asks, given a PN $N$ and a marking $m$, whether $m \in$ Cover($N$). It is EXPSPACE-complete [3].

A fifo system is a tuple $\langle X, x^0, M, \Delta \rangle$ where $X$ is a finite set of (control) states, $x^0 \in X$ is the initial state, $M$ is the message alphabet and $\Delta \subseteq X \times \Sigma \times X$ is the set of transition rules for $\Sigma = \{!?, \rightarrow\} \cup \{\varepsilon\}$. The semantics of a fifo system is given as an infinite transition system over configurations $S = X \times M^*$ where the queue content is represented by a word in $M^*$ that is accessed in a fifo manner. It is well known that the control state reachability problem is undecidable for fifo systems [5].

A two counter system (2Cs) is a tuple $\{X, x^0, \Sigma, \Delta\}$ where $X$ is a finite set of (control) state, $x^0 \in X$ is the initial state, $\Sigma = \{\text{incr}, \text{decr}, \text{ia}_{\text{zero}}\} \times \{1, 2\}$ is the set of actions, and $\Delta \subseteq X \times \Sigma \times X$ is the set of transition rules. The actions incr$(i)$ and decr$(i)$ are interpreted as incrementing and decrementing a counter variable $i$ (for $i = 1, 2$) that has values in $\mathbb{N}$, and testing whether the current counter $i$ equals zero. The semantics of a 2Cs is represented by an infinite LTS with states $S = X \times \mathbb{N} \times \mathbb{N}$. The reachability problem for two counter systems (with zero test) is undecidable [13].

3 Queue-dispatch asynchronous systems

Syntax: We are now ready to define our model for GCD-like programs. Let $D$ be a finite data domain with initial value $d_0$. A queue-dispatch asynchronous system (QDAS) $A$ is a tuple $\langle CQID, SQID, \Gamma, \text{main}, \mathcal{X}, \Sigma, (T S_s)_{s \in \Gamma} \rangle$ where:

- $CQID$ and $SQID$ are respectively finite sets of (c)oncurrent and (s)erial queues;
- $\Gamma$ is the finite set of blocks and main $\in \Gamma$ is the initial block.
- $\mathcal{X}$ is a finite set of $D$-valued variables;
- $\Sigma$ is the set of actions, with $\Sigma = \{\text{dispatch}_s, \text{dispatch}_a\} \times (CQID \cup SQID) \times \Gamma \setminus \{\text{main}\}) \cup \text{guards}(\mathcal{X}) \cup \text{assign}(\mathcal{X})$.
for each \( \gamma \in \Gamma \): \( TS_\gamma \) is a tuple \( \langle S_\gamma, s_0^\gamma, f_\gamma, \Sigma, \Delta_\gamma \rangle \) where \( \langle S_\gamma, s_0^\gamma, \Sigma, \Delta_\gamma \rangle \) is an LTS and \( f_\gamma \in S \) a distinct final state.

We assume that \( SQID, CQID, \Gamma, X \), and all \( S_\gamma \) for \( \gamma \in \Gamma \) are disjoint from each other. We let \( S = \bigcup_{\gamma \in \Gamma} S_\gamma, F = \bigcup_{\gamma \in \Gamma} \{ f_\gamma \}, \Delta = \bigcup_{\gamma \in \Gamma} \Delta_\gamma \), and \( QID = SQID \cup CQID \cup \{ \bot \} \) (where \( \bot \notin SQID \cup CQID \)). We further assume that \( \varepsilon \notin \Sigma \).

Call-task graphs: We formalize the semantics of QDAS using the notion of call-task graph (CTG) to describe the system’s global configurations. A configuration of a QDAS (see Fig. 2) for an example contains a set of running tasks, represented by task vertices (depicted by round nodes) and a set of called but unscheduled blocks, represented by call vertices (square nodes). Call vertices are held by queues, and the linear order of each queue is represented by queue edges (solid edges). Synchronous calls add an additional dependency (the caller is waiting for the termination of the callee) that is represented by a wait edge (dashed edges) between the caller and the callee. Wait edges are also inserted between the head of a serial queue and the running task that has been extracted from this queue (if it exists) to indicate that the task has to terminate before a new block can be dequeued. Note that only vertices without outgoing edges can execute a computation step, the others are currently blocked. Each node \( v \) is labeled by two pieces of information: a block \( \lambda(v) \in \Gamma \), and a queue identifier \( queue(v) \in QID \).

When \( v \) is a call vertex, \( \lambda(v) \) is the queue that contains \( v \), otherwise, \( \lambda(v) \) is the queue that contained \( v \) before it was scheduled. Task vertices are labeled by their current state \( state(v) \) (for convenience, we also label call vertices by the initial state of their respective blocks – not shown in the figure).

Example 2 The CTG in Fig. 2 depicts a configuration of a QDAS with two queues. Queue \( q_2 \) is serial (note the outgoing wait edge to the running task) and contains \( \gamma_2 \gamma_3 \gamma_2 \), and \( q_1 \) is parallel with content \( \gamma_1 \gamma_2 \). There are 4 active tasks, two of them \( main \) and the task running \( \gamma_1 \) are blocked. The task running \( \gamma_3 \) has been dequeued from \( q_2 \) and is currently at location \( s \).

Formally, given a QDAS \( A = \langle CQID, SQID, \Gamma, main, X, \Sigma, (TS_\gamma)_{\gamma \in \Gamma} \rangle \), a call-task graph over \( A \) is a tuple \( G_A = \langle V, E, \lambda, queue, state \rangle \) where: \( V = V_C \cup V_T \) is a finite set of vertices, partitioned into a set \( V_C \) of call vertices and a set \( V_T \) of task vertices; \( E \subseteq V \times V \) is a set of edges; \( \lambda : V \rightarrow \Gamma \) labels each vertex by a block; \( queue : V \rightarrow QID \) associates each vertex to a queue identifier; and \( state : V \rightarrow S \) associates each vertex to an LTS state. For each \( q \in QID \), let \( V_q = \{ v \in V \mid queue(v) = q \} \).

The set \( E \) is partitioned into the set \( E_W \) of wait edges and the set \( E_Q = \bigcup_{q \in QID} E_q \) of queue edges where, for each \( q \in QID \), \( E_q = E \cap (V_q \times V_q) \). A CTG is empty iff \( V = \emptyset \). A path (of length \( n \)) in \( G_A \) is a sequence of vertices \( v_0, v_1, \ldots, v_n \) s.t. for all \( 1 \leq i \leq n \): \( (v_{i-1}, v_i) \in E \). Such a path is simple iff \( v_i \neq v_j \) for all \( 1 \leq i < j \leq n \). The restriction of \( G_A \) to \( V' \subseteq V \) is the CTG \( G'_A = \langle V', E', \lambda', queue', state' \rangle \), where \( E' = E \cap (V' \times V') \), and \( \lambda', queue' \) and \( state' \) are respectively the restrictions of \( \lambda, queue \) and \( state \) to \( V' \).

In the rest of the paper, we assume that all the CTG we consider are well-formed, i.e., they fulfill the following requirements:

1. For each \( v \in V_T \): \( state(v) \in S_{\lambda(v)} \), where \( S_{\lambda(v)} \) are the states of \( TS_{\lambda(v)} \).
2. Each call vertex has at most one outgoing (queue or wait) edge, at most one incoming wait edge and at most one incoming queue edge. Each task vertex has at most one outgoing and at most one incoming wait edge.

3. For each $q \in QID$, the restriction of $G_A$ to $V_q$ is either empty or contains one and only one simple path of length $|V_q| - 1$. Intuitively, this ensures the well-formedness of the queues.

4. For each $q \in SQID$, there is at most one task vertex $v$ s.t. $queue(v) = q$. This ensures that queues in $SQID$ indeed force the serial execution of their members.

For convenience, we also introduce the following notations. Let $A$ be a queue identifier of head and the tail of $v$ exist, and $v$ when they exist, these vertices are necessarily unique because of the well-formedness of the queues.

We finally, $v$ • for all $v$, $\forall v$ where:

$V = E = \emptyset \cup E_2$, where: (i) $E_1 = \{\{v', tail(G_A, q)\}\}$ if $tail(G_A, q) \neq \bot$ and $E_1 = \emptyset$ otherwise and (ii) if $v \in V$ is a task node s.t. $queue(v) = q \in SQID$, then $E_2 = \{\{v', v\}\}$, otherwise $E_2 = \emptyset$. Intuitively, this operation inserts a call to $\gamma$ in the queue $q$, by creating a new vertex $v'$ and adding an edge to maintain the FIFO ordering, if necessary (set $E_1$. In the case of a serial queue that was empty before the enqueue, a supplementary edge (in set $E_2$) might be necessary to ensure that $v'$ is blocked by a currently running $v$ which has been extracted from $q$.

4. For each $q \in QID$, if $head(G_A, q)$ is different from $\bot$ and equal to unblocked, then dequeue($q$)($G_A$) is the CTag $\{V'_C \cup V'_F, E', \lambda, queue, state\}$ where $V'_C = V_C \setminus \{head(G_A, q)\}$ and $V'_F = V'_T \cup \{head(G_A, q)\}$. Otherwise, head($G_A, q$) = $\bot$ and dequeue($q$)($G_A$) is undefined. Intuitively, this operation removes the first (with respect to the FIFO ordering) block from $q$ and turns the corresponding call vertex head($G_A, q$) into a task vertex, meaning that the block is now running as a task.

• for all $\delta = (s, a, s') \in \Delta$, step($\delta$)($G_A$) is a set of CTag defined as follows. $\{V, E, \lambda, queue, state\} \in step(\delta)(G_A)$ iff there exists an unblocked $v \in V_T$ s.t. $state(v) = s$, $state'(v) = s'$ and for all $v' \neq v$: $state'(v') = state(v')$. Remark that
\[ \text{step}(\delta)(G_A) \] can be empty. Intuitively, each graph in \( \text{step}(\delta)(G_A) \) corresponds to the firing of an \( a \)-labeled transition by a task that is not blocked.

- for all unblocked \( v \in V \cup \{ \bot \} \), all \( v' \in V \): \( \text{letwait}(v, v')(G_A) \) is either the C\( T \)\( G \) \( G_A \) \( v = \bot \), or the C\( T \)\( G \) \( \langle V, E \cup \langle v, v' \rangle, \lambda, \text{queue}, \text{state} \rangle \) if \( v \neq \bot \). Intuitively, this operation adds a wait edge between nodes \( v \) and \( v' \) when \( v \neq \bot \), and does not modify the C\( T \)\( G \) otherwise.

**Semantics of QDAS:** For a QDAS \( \mathcal{A} \) with set of variables \( \mathcal{X} \), a configuration is a pair \( (G, d) \), where \( G \) is a C\( T \)\( G \) of \( \mathcal{A} \) and \( d \in \text{vals}(\mathcal{X}) \). The operational semantics of \( \mathcal{A} \) is given as a transition system \( [\mathcal{A}] \) whose states are configurations of \( \mathcal{A} \); and whose transitions reflect the semantics of the actions labeling the transitions of the QDAS. Formally, given a QDAS \( \mathcal{A} = \langle CQID, SQID, \Gamma, \text{main}, \mathcal{X}, \Sigma, (TS_\gamma)_{\gamma \in \Gamma} \rangle \), \( [\mathcal{A}] \) is the labeled transition system \( (C, c^0, \Sigma, \Rightarrow) \) where: (i) \( C \) contains all the pairs \( (G, d) \) where \( d \in \text{vals}(\mathcal{X}) \), and \( G \) is a C\( T \)\( G \) of \( \mathcal{A} \), (ii) \( c^0 = (G^0, d^0) \) with \( d^0(x) = d_0 \) for all \( x \in \mathcal{X} \), and \( G^0 = \langle \{v^0\}, \emptyset, \text{queue}, \text{state} \rangle \), where \( v^0 \) is a task node, \( \lambda(v^0) = \text{main}, \text{state}(v^0) = s^0_{\text{main}} \) and \( \text{queue}(v^0) = \bot \), (iii) \( \Sigma = \Sigma \cup \{\varepsilon\} \) and \( (G, d), a, (G', d') \) \( \Rightarrow \) \( \Rightarrow \) one of the following holds:

**Async. dispatch:** \( a = \text{dispatch}_a(q, \gamma), d' = d \), and there are \( \delta = (s, a, s') \in \Delta \) and \( G'' \in \text{step}(\delta)(G) \) s.t.: \( G' = \text{enqueue}(q, \gamma)(G'') \).

**Sync. dispatch:** \( a = \text{dispatch}_a(q, \gamma), d' = d \), and there are \( \delta = (s, a, s') \in \Delta \) and \( G'' \in \text{step}(\delta)(G) \) s.t.: \( G' = \text{letwait}(v, v')(\text{enqueue}(q, \gamma)(G'')) \) where \( v \) is the node whose state has changed during the \text{step} operation, and \( v' \) is the fresh node that has been created by the \text{enqueue} operation. That is, a queue vertex \( v' \) labeled by \( \gamma \) is added to \( q \) and a wait edge is added between the node \( v \) representing the task that performs the synchronous dispatch, and \( v' \), as the dispatch is synchronous.

**Test:** \( a = g \in \text{guards}(\mathcal{X}), d' = d, d \models g \), and there is \( \delta = (s, a, s') \in \Delta \) s.t. \( G' \in \text{step}(\delta)(G) \).

**Assignment:** \( a = x \leftarrow v \in \text{assign}(\mathcal{X}), d'(x) = v \), for all \( x' \neq x \): \( d'(x) = d(x) \) and there is \( \delta = (s, a, s') \in \Delta \) s.t. \( G' \in \text{step}(\delta)(G) \).

**Scheduler action:** \( a = \varepsilon, d' = d \) and:

- either there is a final vertex \( v \) s.t. \( G' = G \setminus v \);
- or there is \( q \in CQID \) s.t. \( \text{head}(q, G) \neq \bot \) and \( G' = \text{dequeue}(q)(G) \).
  That is, the scheduler schedules a block (represented by \( v \)) from a concurrent queue.
- or there is \( q \in SQID \) s.t. \( \text{head}(q, G) = v \), \( G' = \text{letwait}(\text{head}(q, G''), v)(G'') \), \( G'' = \text{dequeue}(q)(G) \) and \( v \) is unblocked. That is, the scheduler schedules a block (represented by \( v \)) from the serial queue \( q \). As the queue is serial, a wait edge is inserted between the next waiting block in \( q \) (now represented by \( \text{head}(q, G'') \)) and \( v \).
A run $\rho$ of a QDAS is a finite alternating sequence $c_0a_1c_1a_2 \ldots a_nc_n$ of configurations and actions where $(c_i, a_{i+1}, c_{i+1}) \in \rightarrow$ for all $0 \leq i < n$ and $c_0 = c^0$. A configuration $c$ is reachable in $\mathcal{A}$ iff there exists a run $c_0a_1c_1a_2 \ldots a_nc_n$ of $\mathcal{A}$ s.t. $c_n = c$. We denote by $\text{Reach}(\mathcal{A})$ the set of all reachable configurations of $\mathcal{A}$.

The decision problem on QDAS we consider in this work is the Parikh coverability problem. The Parikh image $\text{Parikh}(G)$, of a CTG $G$ of $\mathcal{A}$ with set of states $S$, is a function $f : S \rightarrow \mathbb{N}$, s.t. for all $s \in S$: $f(s) = |\{v \in V | \text{state}(v) = s\}|$. Given two Parikh images $\text{Parikh}(G)$ and $\text{Parikh}(G')$, we let $\text{Parikh}(G) \leq \text{Parikh}(G')$ iff for all $s \in S$: $\text{Parikh}(G)(s) \leq \text{Parikh}(G')(s)$. Then, the Parikh coverability problem asks, given a QDAS $\mathcal{A}$ with set of locations $S$ and a function $f : S \rightarrow \mathbb{N}$, whether there is $c = (G, d) \in \text{Reach}(\mathcal{A})$ s.t. $f \preceq \text{Parikh}(G)$. When the answer to this question is ‘yes’, we say that $f$ is Parikh-coverable in $\mathcal{A}$. As recalled in the introduction, meaningful verification questions can be reduced to this problem. For instance, consider a mutual exclusion question, asking whether it is possible to reach, in a QDAS $\mathcal{A}$, a configuration in which at least two tasks are executing the same block $\gamma$ and are in the same control state $s$. This can be encoded into an instance of the Parikh coverability problem, where $f(s) = 2$ and $f(s') = 0$ for all $s' \neq s$.

4 The Parikh coverability problem

In this section, we study the Parikh coverability problem from a computational point of view. As expected, this problem is undecidable in general. However, when restricting the types of queues and dispatches that are allowed, it is possible to retain decidability.

In these cases, we characterize the complexity of the problem. Formally, we consider the following subclasses of QDAS. A QDAS $\mathcal{A}$ with set of transitions $\Delta$, set of serial queues $\text{SQID}$ and set of concurrent queues $\text{CQID}$, is synchronous iff there exists no $(s, a, s') \in \Delta$ with $a \in \{\text{dispatch}_a\} \times \text{CQID} \times \Gamma$; it is asynchronous iff there exists no $(s, a, s') \in \Delta$ with $a \in \{\text{dispatch}_a\} \times \text{CQID} \times \Gamma$; it is concurrent iff $\text{SQID} = \emptyset$ and $\text{CQID} \neq \emptyset$; it is serial iff $\text{CQID} = \emptyset$ and $\text{SQID} \neq \emptyset$; it is queueless iff $\text{CQID} = \text{SQID} = \emptyset$.

**Queueless QDAS:** In a queueless QDAS, there is no dispatch possible, so the only task that can execute at all time is the main one. Thus, configurations of queueless QDAS can be encoded as tuples $(s, d)$, where $s$ is a state of main, and $d$ is a valuation of the variables. Hence queueless QDAS are essentially LTS with variables over a finite data domain, thus:

**Proposition 2** The Parikh coverability is PSPACE-C for queueless QDAS.

**Synchronous QDAS:** In synchronous QDAS, there is no concurrency, i.e. in all reachable configurations there is at most one running task that can execute a transition. All the other tasks have necessarily performed a synchronous dispatch and are thus blocked. More precisely, in reachable configuration $(G, d)$ of a synchronous QDAS, $G$ is of one of the forms depicted in Fig.4 (i.e. $v_0, \ldots, v_n \in V_T$ and either $v_n \in V_T$ or $v_n \in V_C$). When the current CTG is of the form Fig.4(a), the only possible
that covers \( f \) amounts to finding a reachable configuration \( (s_i, w_i, d_i) \) of \( \mathcal{P}_A \) s.t. the
Parikh image $P$ of $w_i \cdot s_i$ is s.t. $f \leq P$ (as the CTG is encoded by $w_i \cdot s_i$). To achieve this, we augment $P_A$ with a widget that works as follows. In any location of $P_A$, we can jump non-deterministically to the widget. This jump pushes the current location to the stack so that, when entering the widget, the CTG is completely described by the stack content only. Then, the widget pops all the values from the stack, and checks that at least $f(s)$ symbols $s$ are present on the stack. The widget jumps to an accepting state iff it is the case. We call $P_{A,f}$ the resulting PDS. Clearly, one can build such a widget for all $f$, and this effectively reduces the Parikh coverability problem of QDAS to the location reachability problem of PDS. Moreover, for all $f$, the widget is of size exponential in $|S|$ and exponential in the binary encoding of $\max_{s \in S} f(s)$. Hence, building $P_{A,f}$ requires exponential time:

**Proposition 4** Given a synchronous QDAS $A$ with states $S$ and a function $f : S \to \mathbb{N}$, one can generate a PDS $P_{A,f}$ of size exponential in $A$ and a state $s$ of $P_{A,f}$, s.t. $P_{A,f}$ reaches $s$ iff $f$ is Parikh coverable in $A$.

As testing emptiness of a pushdown system is in PTIME, the Parikh coverability problem is in ExPTIME for synchronous QDAS (with both types of queues). A matching lower bound is obtained by reducing the reachability question of PDS with data (see Proposition 1). This reduction requires only one concurrent queue, so the Parikh reachability problem is ExPTIME-hard for synchronous concurrent QDAS. Hence:

**Theorem 1** The Parikh coverability problem is ExPTIME-C for synchronous and for synchronous concurrent QDAS.

Let us take a closer look on the dispatches that happen in runs of synchronous QDAS that have only serial queues. Assume a run of such a QDAS, and suppose the first dispatch performed along this run (by main) is dispatch$_s(q, \gamma)$. As the dispatch is synchronous, main is blocked, and the scheduler has to dequeue $\gamma$ to let the system progress. Clearly, if $\gamma$ performs a synchronous dispatch dispatch$_s(q, \gamma')$ to the same queue $q$, we reach a deadlock. Indeed, the task running $\gamma$ is blocked by the synchronous dispatch of $\gamma'$, but we need to wait for the termination of $\gamma$ to be able to dequeue $\gamma'$ from $q$ (because $q$ is serial). So, $\gamma$ has to dispatch its blocks to other queues. For the same reason, we also reach a deadlock if a block called by $\gamma$ performs a synchronous dispatch into $q$. We conclude that, in all reachable CTG, the following holds for all queues: either the queue contains one block and there is no running task from this queue, or the queue is empty, and there is at most one running task from this queue. Hence, all the reachable CTG have at most $|SQID| + 2$ vertices. Thus, the pushdown systems used in all previous constructions have bounded stack height and we can apply the emptiness test on a finite state system when proving Proposition 2. The lower bound can be derived from Proposition 1.

**Theorem 2** The Parikh coverability problem is PSPACE-C for serial synchronous QDAS.

**Concurrent asynchronous QDAS:** Let us now establish a relationship between concurrent asynchronous QDAS and Petri nets that prove that the Parikh coverability problem is ExPSpace-complete. We first show how to reduce the QDAS Parikh coverability problem to the Petri net coverability problem. Let $A = \langle CQID, \emptyset, \Gamma, \text{main}, \mathcal{X}, \Sigma, \rangle$.
be a concurrent asynchronous QDAS on domain \( \mathbb{D} \). We associate to \( \mathcal{A} \) the PN \( \mathcal{N}_A = \langle P, T, m_0 \rangle \) where: \( P = \{X \times \mathbb{D}\} \cup \mathbb{S}, t = (I_t, O_t) \in T \) iff one of the following holds:

**Async. dispatch:** there exists \((s, (\text{dispatch}_a, q, \gamma), s') \in \Delta \) s.t. \( I_t(p) = 1 \) iff \( p = s \) and \( O_t(p) = 1 \) iff \( p \in \{s', s''\} \).

**Test:** there exists \((s, x = v, s') \in \Delta\) where \( x = v \in \text{guards}(\mathcal{X}) \) s.t. \( I_t(p) = 1 \) iff \( p \in \{(x, v), s\} \) and \( O_t(p) = 1 \) iff \( p \in \{(x, v), s'\} \).

**Assignment:** there exists \((s, a, s') \in \Delta \) with \( a = x \leftarrow v \in \text{assign}(\mathcal{X}) \) and \( v' \in \mathbb{D} \) s.t. \( I_t(p) = 1 \) iff \( p \in \{(x, v'), s\} \) and \( O_t(p) = 1 \) iff \( p \in \{(x, v'), s'\} \).

**Task termination:** there exists \( \gamma \in \Gamma \) s.t. \( I_t(p) = 1 \) iff \( p = f_\gamma \) and for all \( p \in P \):

\[
O_t(p) = 0.
\]

and finally, \( m_0(s^0_{\text{main}}) = 1 \), for all \( x \in \mathcal{X} \): \( m_0(x, d_0) = 1 \) and for all \( p \in P \setminus \{s^0_{\text{main}}\} \cup \{(x, d_0) | x \in \mathcal{X}\} : m_0(p) = 0 \).

The intuition behind the construction is as follows. Each place \( s \in \mathcal{S} \) counts how many blocks are currently running and in state \( s \). Each place \((x, d)\) encodes the fact that variable \( x \) contains value \( d \) in the current valuation. Remark that we have no place to encode the contents of the queue, as the dispatch of block \( \gamma \) directly creates a new token in \( s^0_\gamma \). This encoding is, however, correct with respect to the Parikh coverability problem, as Parikh(\( G \)) does not distinguish between a block \( \gamma \) that is waiting in a queue, and a task executing \( \gamma \) in its initial state. Thus:

**Proposition 5** For all concurrent asynchronous QDAS \( \mathcal{A} \) with set of location \( S \), we can build, in polynomial time, a PN \( \mathcal{N}_A \) s.t. \( f \) is Parikh-coverable in \( \mathcal{A} \) iff \( m \) is the marking s.t. for all \( s \in S \): \( m(s) = f(s) \) and for all \( p \in P \setminus S \): \( m(p) = 0 \).

Let us now reduce the Petri net coverability problem to the QDAS Parikh coverability problem. Let \( N = \langle P, T, m_0 \rangle \) be a PN. We associate to \( N \) the concurrent asynchronous QDAS \( \mathcal{A}_N = \langle \text{CQID}, 0, \Gamma, \text{main}, \mathcal{X}, \Sigma, (\mathcal{T}_\gamma)_{\gamma \in \Gamma} \rangle \), on the finite domain \( \mathbb{D} = \{0, 1\} \), where \( \text{CQID} = \{C\}, \Gamma = \{\text{main}, \text{trans}\} \cup P, \mathcal{X} = \{v_p | p \in P\} \) and \( (\mathcal{T}_\gamma)_{\gamma \in \Gamma} \) is given by the pseudo-code in Fig. 4 (this construction is an extension of a construction found in [9]). We assume that, for \( \gamma \in \{\text{trans}, \text{main}\} \): \( s^\gamma_p \) is the location of \( \mathcal{T}_\gamma \) that is reached when the control reaches line \( \ell \). Let \( G = \langle V, E, \lambda, \text{queue}, \text{state} \rangle \) be a Ctg for \( \mathcal{A}_N \), and let \( m \) be a marking of \( N \). Then, we say that \( G \) encodes \( m \), written \( G \triangleright m \) iff (i) Parikh(\( G \))(\( s_{\text{trans}} \)) = Parikh(\( G \))(\( s_{\text{main}} \)) = 1, (ii) for all \( p \in P \): Parikh(\( G \))(\( s^0_p \)) = \( m(p) \), and (iii) for all \( p \in P \), for all \( s \in S_p \setminus \{s^0_p \} \): Parikh(\( G \))(\( s \)) = 0. Thus, intuitively, a Ctg \( G \) encodes a marking \( m \) if \( \text{main} \) is at line 8, \( \text{trans} \) is at line 14, \( m(p) \) counts the number of \( p \) blocks that are either in \( C \) or executing but at their initial state, and there are no \( p \) blocks that are in state \( s^{\text{mid}}_p \) or \( s^{\text{fin}}_p \).

The intuition behind the construction is as follows. Each run of the QDAS \( \mathcal{A}_N \) starts with an initialization phase, where \( \text{main} \) initializes all the \( v_p \) variables to 0 and dispatches, for all \( p \in P \), \( k_p \) blocks \( p \) with \( k_p \leq m_0(p) \), then dispatches a call to
trans. At that point, the only possible action is that the scheduler dequeues all the blocks. All the \( p \) tasks are then blocked, as they need that \( v_p = 1 \) to proceed and terminate. Then, \( \text{trans} \) cyclically picks a transition \( t \), sets to 1 all the variables \( v_p \), s.t. \( t \) consumes a token in \( p \), and waits that all the \( v_p \) variables return to 0. This can only happen because at least \( I_t(p) \) \( p \) tasks have terminated, for all \( p \in P \). So, when \( \text{trans} \) reaches line 19, the encoded marking has been decreased by at least \( I_t \). Remark that more than \( I_t(p) \) \( p \) tasks could terminate, as they run concurrently, and the lines 11 and 12 do not execute atomically. Then, \( \text{trans} \) dispatches one new \( \text{block} \) block if \( t \) produces a token in \( p \). This increases the encoded marking by \( O_t \), so the effect of one iteration of the main while loop of \( \text{trans} \) is to simulate the effect of \( t \), plus a possible token loss. Hence, the resulting marking is guaranteed to be in \( \text{Cover}(N) \) (but maybe not in \( \text{Reach}(N) \)). This is formalized by the following proposition:

**Proposition 6** For all PN \( N \), we can build, in polynomial time, a concurrent asynchronous QDAS \( A_N \) s.t. \( m \in \text{Cover}(N) \) iff there exists \((G, d) \in \text{Reach}(A_N)\) with \( G \sqsupseteq m \).

**Theorem 3** The Parikh coverability problem is \textsc{ExpSpace}-complete for concurrent asynchronous QDAS.

**Asynchronous Serial QDAS:** Let us show that for the class of QDAS with one serial queue, and where asynchronous dispatches are allowed, the Parikh coverability problem is undecidable. We establish this by a reduction from the control-state reachability problem in a fifo system. Let \( F = (S_F, s_F^0, M, \Delta_F) \) be a fifo system and let \( c \in S_F \) be a control state whose reachability has to be tested. We build the asynchronous serial QDAS \( A_F = (\emptyset, \{q\}, \Gamma, \text{main}, \mathcal{X}, \Sigma, (\mathcal{T}S_\gamma)_{\gamma \in \Gamma}) \) on domain \( D = M \cup S_F \cup \{\varepsilon\} \), where \( \Gamma = M \cup \{\varepsilon, \text{main}\} \), \( \mathcal{X} = \{\text{state, head}\} \) and the \( \mathcal{T}S_\gamma \) are sketched in Fig. 5.

Intuitively, runs of \( A_F \) simulate the runs of \( F \), by encoding the current state of \( F \) in variable \( \text{state} \) and the content of \( F \)'s queue into the content of the serial queue \( q \). More precisely, it easy to check that, once \text{main} has reached line 8, all the \( \text{CTG} \) that are reached in \( A_F \) are of either shapes depicted in Fig. 5 for \( \{m_1, \ldots, m_n, m\} \subseteq M \cup \{\varepsilon\} \). That is, there are at most two running tasks: \text{main} and possibly one task running a \( m \) block (for \( m \in M \cup \{\varepsilon\} \)), that has to terminate to allow a further dequeue from \( q \). This is because \( q \) is a serial queue and all the dispatches are asynchronous. When the \( \text{CTG} \) is of shape (b), the duty of the running \( m \) block is to simulate a step of \( F \). It runs an infinite while loop (line 11 onwards – ignore the test at line 10 for the moment), that

```plaintext
def main():
    for each p ∈ P:
        v_p := 0
    select k_p ∈ \{0, \ldots, m_0(p)\}
    for i = 0...k_p:
        dispatch_a(C, p())
    dispatch_a(C, trans())
    while(true):
        for each p ∈ P s.t. I_t(p) = 1:
            v_p := true
        while(∃p ∈ P: v_p = 1):
            do nothing
        for each p ∈ P s.t. O_t(p) = 1:
            dispatch_a(C, p())

block p(): // For all p ∈ P
    while(v_p = 0):
        do nothing
    v_p := 0

Figure 4: Encoding of PN coverability \((P, T, m_0)\) by a QDAS
```
Note that the reachability of a state $c$ of the fifo system is explicitly coded into the control structure.

Figure 5: Fifo system encoding into a serial asynchronous QDAS; two types of CTG in this case

(i) tests whether $c$ has been reached (line 12) and jumps to line 21 if it is the case; (ii) guesses a transition $(s,a,s')$ of $F$; and (iii) checks that the guessed transition is indeed fireable from the current configuration of $F$, and, if yes, simulate it. This consists in, first testing that $s$ is the current state (line 14). If not, the block jumps to the infinite loop of line 20, which ends the simulation. Otherwise, the current state is updates to $s'$, and the channel operation is then simulated. A send of message $n$ is simulated (line 16) by an asynchronous dispatch of block $n$ to $q$. The simulation of a receive of $n$ from $q$ is more involved, as only the scheduler can decide to dequeue a block from $q$, and this can happen only if the current running block terminates (line 19). Still, we have to check that message $n$ is indeed in the head of $q$. This is achieved by setting global variable head to $n$, and letting the next dequeued block check that itself encodes the value stored into head. This is performed at line 10. If this test is not satisfied, the block jumps to the infinite loop of line 20, and the simulation ends. Otherwise, it proceeds with the simulation. Thus, in all reachable configurations of $A_P$, a block $m$ (with $m \in M \cup \{\varepsilon\}$ will reach line 21 iff $c$ is reachable in $F$. This effectively reduces the control location reachability of fifo systems to the Parikh coverability problem of serial asynchronous QDAS.

**Theorem 4** The Parikh coverability problem is undecidable for asynchronous QDAS with at least one serial queue.

**Concurrent QDAS:** Let us show that, once we allow both synchronous and asynchronous dispatches in a concurrent QDAS, the Parikh coverability problem becomes undecidable too. For that purpose, we reduce the reachability problem of two counter systems to the Parikh coverability problem of concurrent QDAS. Let us give the intuition of the construction. For each two counter system $P$, we construct a QDAS $A_P$ s.t. all reachable CTG in $A_P$ encode configurations of $P$ and are of the form depicted in Fig. 6. That is, (after an initialization phase), there are always three tasks that are unblocked: a main task to simulate $P$’s control structure, and, for each $i = \{1, 2\}$,
Figure 6: From a two counter system to a QDAS: main and null(i), zero(i) for i = 1, 2

either a task eins(i) or a task null(i). If the task null(i) is unblocked, then counter i is zero in the current configuration of \( \mathcal{P} \). Otherwise, the current valuation of counter i is encoded by the number of eins(i) tasks in the CTG. Remark that, as in the case of synchronous QDAS, the parts of the CTG that encode each counter behave as pushdown stacks. Finally, the control location of \( \mathcal{P} \) is recorded in global variable state.

The actual operations on the counters will be simulated by the eins(i) and null(i) running tasks. As main simulates the control structure, we need to synchronize main with those eins(i) and null(i) tasks. Let us explain intuitively how we can achieve rendezvous synchronization between running tasks using global variables of QDAS. Consider a QDAS with three global variables \( \ell_1, \ell_2 \) ranging over the Boolean and a global variable \( x \) ranging over a finite set of ‘messages’ \( M \). Let \( \gamma_1 \) and \( \gamma_2 \) be two blocks whose LTS are:

\[
\gamma_1:\quad \text{null}(i): \quad \text{eins}(i):
\]

Assume a configuration \( c \) of the QDAS where \( \ell_1 = \ell_2 = 0 \) and where two distinct tasks are running \( \gamma_1 \) and \( \gamma_2 \), are unblocked, and are in \( s_0 \) and \( s_0' \) respectively. Assume that no other task can access \( \ell_1, \ell_2 \) and \( x \). It is easy to check that, from \( c \), there is only one possible interleaving of the transitions of \( \gamma_1 \) and \( \gamma_2 \). So if \( \gamma_2 \) reaches \( s_5' \) from \( c \), then \( \gamma_1 \) must have reached \( s_5 \), and the \( x = m \) test in \( \gamma_1 \) has been fired after the \( x = m \) assignment in \( \gamma_2 \). This achieves rendezvous synchronisation between \( \gamma_1 \) and \( \gamma_2 \), with the passing of message \( m \). This can easily be extended to rendezvous via different “channels”, by duplicating those global variables. So, we extend the syntax of QDAS by allowing transitions of the form \((s_0, e!m, s_5)\) and \((s_0', e?m, s_5')\) (for \( m \in M \)) to denote respectively a send and a receive of message \( m \) on a rendezvous channel \( e \).

We rely on this mechanism to let main send operations to be performed on the counters to the null(i) and eins(i) running tasks. More precisely, for a 2CS \( \mathcal{P} = (X, x^0, \Sigma_\mathcal{P}, \Delta_\mathcal{P}) \), we build the QDAS \( \mathcal{A}_\mathcal{P} = (CQID, \emptyset, \Gamma, \text{main}, X, \Sigma, (TS_\gamma)_{\gamma \in \Gamma}) \) where \( CQID = \{q\}, \Gamma = \{\{\text{null}, \text{eins}\} \times \{1, 2\}\} \cup \{\text{main}\}, X = \{\ell_1, \ell_2, x, x_1^2, x_1^2, x_2^2\} \).
where $x^1, x^2$ range over the domain \{incr, decr, is_zero, ack\}, and the transition systems are given in Fig. 6. The variables $X$ encode two channels that we call 1 and 2 in the pseudo code of Fig. 6. The main task runs an infinite while loop (line 12 onwards) that consists in guessing a transition $(s, a, s')$ of $F$ and synchronising, via rendezvous on the channels 1 and 2, with the relevant null or eins unblocked task, to let it execute the operation on the counter. When a null(i) or eins(i) receives an incr message, it performs a synchronous dispatch of eins(i) into $q$ to increment counter $i$, and acknowledges the operation to main, thanks to message ack. When an eins block receives a decr message, it terminates, which decrements the counter. null blocks cannot receive decr messages, so, if main requests a decr operation when the counter is zero, main gets blocked. This means that the guessed transition was not fireable in the currently simulated 2CS configuration, and ends the simulation. Finally, only null blocks can receive and acknowledge is_zero messages, so, again, main is blocked after sending is_zero to a non-zero counter. Note that we need both asynchronous calls to start two counters in parallel, and synchronous calls to encode the counter values.

It is easy to check that $P$ reaches a state $x \in X$ iff $f$ is coverable in $A_P$ where $f(x) = 1$ and $f(x') = 0$ for all $x \in X \setminus \{x\}$. Hence:

**Theorem 5** *The Parikh coverability problem is undecidable for concurrent QDAS that use both synchronous and asynchronous dispatches.*

**References**

A  Proof for Section 2

**Proposition 1**  
*The reachability problem is EXP-Time-C for PDS with data.*

*Proof.*  
For the upper bound, we generate a reachability-equivalent PDS (without data) by encoding all possible data valuations into the pushdown system’s states. This leads to an exponential blowup of the state space. The lower bound can be derived from the reduction of the emptiness test of the intersection of a context-free language with $n$ regular languages that is known to be EXP-Time-hard (hardness follows easily by a reduction from linearly bounded alternating Turing machines; a closely related problem, the reachability of pushdown systems with checkpoints, is shown to be EXP-Time-hard in (*)).

B  Proofs of Section 4

B.1  Synchronous QDAS

**Proposition 3**  
*Let $A$ be a QDAS, and let $P_A$ be the PDS with data built from $A$. There is a run $\rho = c_0a_1c_1 \ldots a_n c_n$ of $A$ if and only if there is a run $\pi = x_0a'_1x_1 \ldots a'_n x_n$ in $P_A$ s.t. for all $0 \leq i \leq n$: $x_i \triangleright c_i$.*

*Proof.*  
We assume that $A = (CQID, SQID, \Gamma, \text{main}, X, \Sigma, (TS_\gamma)_{\gamma \in \Gamma})$ (where, as usual, $S$ denotes the set of all states of $A$), and that $P_A = (Y, X, y^0, S, \Sigma_P, \Delta_P)$. For convenience, we rewrite configurations $(y, w, d) \in Y \times \Sigma^* \times \mathbb{D}^X$ of $P_A$ as pairs $(x, d) \in S^* \times \mathbb{D}^X$ where $x = w \cdot y$ encodes both the current location and the stack content. Thus, with this new notation, we have $(x, d) \triangleright (G, d)$ iff $x \triangleright G$ and $d = d$.

Let us prove the first implication. Let $(G_0, d_0)a_1(G_1, d_1)a_2 \ldots a_n(G_n, d_n)$ be a run of $A$. Let us show how to build a run $(x_0, \widehat{d}_0)a_1(x_1, \widehat{d}_1)a_2 \ldots a_n(x_n, \widehat{d}_n)$ of $P_A$ such that $(x_i, \widehat{d}_i) \triangleright (G_i, d_i)$ for all $i$.

The construction is by induction on the length of the run of $A$. By construction of $P_A$, $G_0 \triangleright x_0$ and $d_0 = \widehat{d}_0$. We now assume that there exists a prefix of the QDAS’s run of length $0 \leq j \leq n$ of the form $(G_0, d_0) \ldots (G_j, d_j)$ such that there exists a run of the pushdown system $(x_0, \widehat{d}_0) \ldots (x_j, \widehat{d}_j)$ that fulfills the induction hypothesis. We now consider the outcome of a QDAS transition labeled $a_{j+1}$. We know that $G_j$ must be a path of vertices $v_0 \ldots v_n$ connected by wait edges.

**Sync. dispatch:**  
dispatching a block $\gamma$ on queue $q$ leads to $(G_{j+1}, d_{j+1})$ with $d_j = d_{j+1}$ and $G_{j+1}$ is a path graph $v_0 v_1 \ldots v_n v_{n+1}$ with new distinct vertex $v_{n+1}$ where $\text{state}(v_{n+1}) = v_0^0$. We mapped the dispatch rule to a push of the current state to the pushdown and jumping to the new initial state, i.e., we go from $(x_j, \widehat{d}_j)$ to $(x_{j+1}, \widehat{d}_{j+1})$ where $\widehat{d}_j = \widehat{d}_{j+1}$ and $x_{j+1} = x_j \cdot s^0_\gamma$. Obviously, $x_{j+1} \triangleright G_{j+1}$.  

19
**Test/Assignment:** $G_{j+1}$ equals $G_j$ except for $\text{state}_j(v_n) = s$ and $\text{state}_{j+1}(v_n) = s'$ and a possible change of $d_{j+1}$ according to the underlying data action. Executing the same action on $\mathcal{P}_A$ assures that $d_{j+1} = d_j$ and changing the control state of the pushdown only changes $x_j = w \cdot s$ to $x_{j+1} = w \cdot s'$; thus, $x_{j+1} \triangleright G_{j+1}$.

**Termination:** To apply the action $G_j$ consists of a (non-empty) path ending in $v$ with $\text{state}_j(v) \in F$ and $G_{j+1} = G_j \setminus v$, and $d_j = d_{j+1}$. Note that $G_{j+1}$ could be possibly empty. Given a $(x_j, d_j)$ according to the induction hypothesis, then we have to consider two cases: either $x_j = w \cdot y_j$ with $y_j \in S^+$ and $y_j \in S$ (i.e., there is at least one element on the stack), or $x_j = y_j \in S$ (i.e., stack is empty). In the second case, we know that $x_j \in S_{\text{main}}$ and by the induction hypothesis, that $x_j = s_0^0$ and $G_j$ a path of length 1. Now, $\mathcal{P}_A$ takes the empty transition leading to the (bottom) state $e$, i.e., $x_{j+1} = e$, hence $G_{j+1}$ is empty and $e \triangleright G_{j+1}$. If the stack is not empty, then we can take a pop transition such that $x_{j+1} = w \in S^+$ for $x_j = w \cdot s$, hence $x_{j+1} \triangleright G_{j+1}$. Obviously $d_{j+1} = d_j = d_{j+1}$.

(Recall that we asserted dispatch and scheduling to be atomic, so we do not need to consider other actions of the scheduler.)

The reverse direction follows analogously. □

**Lemma 1** Given a finite set $S$ and a function $f : S \rightarrow \mathbb{N}$, then there exists a finite automaton $\mathcal{F}_f$ with alphabet $S$ of size exponential in $|S|$ and polynomial in $\max_{s \in S} f(s)$ such that $L(\mathcal{F}_f) = \{w \in S^* : |w|_s \geq f(s) \text{ for all } s \in S\}$.

**Proof.** Given a set $S$ and a function $f : S \rightarrow \mathbb{N}$, let $k = \max_{s \in S} f(s)$ (which must exists as $S$ is finite). Then $\mathcal{F}_f$ is the finite automaton $\langle Q, S, q^0, \Delta, q_f \rangle$ with states $Q = \{0 \ldots k \}^S$ (interpreted as an $S$-indexed vector of values in $0 \ldots k$), an action alphabet $S$, the initial state is $q^0$ where $q^0(s) = f(s)$, the final state is $q_f$ where $q_f(s) = 0$. The transitions of $\mathcal{F}_f$ are defined as follows: $(q, s, q') \in \Delta$ iff $q'(s) = q(s) - 1$ for $q(s) > 1$, else $q'(s) = q(s)$, and for all $t \in S \setminus \{s\}$ we have $q'(t) = q(t)$. Thus each transition labeled by an action $s$ reduces the “counter” $q(s)$ by one until zero and once arrived at zero, the counter $q(s)$ remains zero for any further $s$ action. Further, the control structure of $\mathcal{F}_f$ is acyclic (except for the loops at $q_f$), thus each run can visit each state in $Q \setminus \{q_f\}$.

If $w = a_1 \ldots a_n \in L(\mathcal{A})$ then it was accepted by a run $q_0a_1q_1 \ldots a_nq_n$ where $q_0 = q^0$ and $q_n = q_f$. Due to our construction of $\Delta$, it holds for $w = a_1 \ldots a_n$ that $|w|_s \geq \min_{s \in S} f(s)$ for all $s \in S$. If $w \notin L(\mathcal{A})$ then there exists a run $q_0a_1q_1 \ldots a_nq_n$ where $q_0 = q^0$ and for $q_n \neq q_f$ it holds that there exists at least one $s \in S$ such that $q_n(s) > 0$, each transition $(q_{i-1}, a_i, q_i)$ assures that $q_i(s) \geq q_i(s)$, hence $|w|_s < f(s)$ for at least one $s \in S$.

**Proposition 4** Given a synchronous QDAS $\mathcal{A}$ with states $S$ and a function $f : S \rightarrow \mathbb{N}$, one can generate a PDS $\mathcal{P}_{\mathcal{A}, f}$ of size exponential in $\mathcal{A}$ and a state $s$ of $\mathcal{P}_{\mathcal{A}, f}$, s.t. $\mathcal{P}_{\mathcal{A}, f}$ reaches $s$ iff $f$ is Parikh coverable in $\mathcal{A}$.
Given into the PDS preamble of Proposition 3. Then, we translate the PDS system’s behaviour with respect to the stack but only internal actions.

Proof. First, we construct the PDS with data \( P_A \) and states \( S \) as explained in the preamble of Proposition 3. Then, we translate the PDS with data to a bisimilar PDS without data \( \hat{P}_A = (\hat{Y}, y^0, \hat{\Phi}, \hat{\Sigma}, \hat{\Delta}) \) by encoding all possible valuations of variables into the PDS’s states by a standard product construction, i.e., \( \hat{Y} = S \times (\mathcal{X} \times D) \).

Given \( y \in \hat{Y} \), let \( S(y) \in S \) denote the original state component. Note: \( \hat{P}_A \) is at most exponentially larger as \( P_A \) and this construction does not change the pushdown system’s behaviour with respect to the stack but only internal actions.

Second, from the function \( f \), we construct the automaton \( \mathcal{F}_f = (Q, S, q^0, \Delta_f, q^f) \) as explained in Lemma I above.

Finally, we define the PDS \( \hat{P}_{A,f} = (Y, y^0, \hat{\Phi}, \Delta_{A,f}) \) as follows

- states are \( Y = \hat{Y} \cup Q \) (assuring disjointness by relabeling when necessary)
- \( y^0 = y^0 \) is the initial state
- \( \hat{\Phi} = \Phi \) is the stack alphabet (where \( \hat{\Phi} = S \) due to the above construction)
- \( \hat{\Sigma} = \hat{\Sigma} \cup \{\epsilon\} \)
- a tuple \( (y, a, y') \) is a rule in \( \Delta_{A,f} \subseteq Y \times \Sigma \times Y \) iff one of the following holds
  - \( (y, a, y') \in \hat{\Delta} \) (include all transition rules of \( \hat{P}_A \));
  - \( a = \text{pop}(s) \) for \( s \in \hat{\Phi} \) and \( (q, s, q') \in \Delta_f \) (include rules of \( \mathcal{F}_f \) and change an \( s \) action to \( \text{pop}(s) \) for \( s \in S \));
  - \( y \in \hat{Y}, a = \text{push}(z) \) for \( z = S(y) \), and \( y' = q^0 \) (connect all states in \( \hat{Y} \) with the initial state of \( \mathcal{F}_f \), additionally stocking the current “state”-component on the stack).

Note that \( \hat{P}_{A,f} \) is of size exponential with respect to both the QDAS and \( f \) due to serial composition.

We now have to show that if there is a run in \( \hat{P}_{A,f} \) that reaches the state \( q^f \), then there exists configuration \( c = (G, d) \) of \( \mathcal{A} \) such that \( f \preceq \text{Parikh}(G) \).

Assume that there exists a run of \( \hat{P}_{A,f} \) reaching \( q^f \), then it must be of the following form \( (x_0, a_1, x_1, \ldots, a_k, x_k, a_{k+1}, x_{k+1}, a_{k+2}, \ldots, a_n, x_n) \) where \( x_i = (y_i, w_i) \subseteq Y \times S^* \) are the corresponding infinite transition system configurations. Further, \( y_0 = y^0, y_n = q^f, y_{k+1} = q^0, \) and \( \{y_1 \ldots y_k\} \) is a subrun that only uses states in \( \hat{Y} \) as well as transitions in \( \hat{P}_A \): \( \{y_{k+1}, \ldots, y_n\} \subseteq Q \) and the corresponding transitions are derived from \( \Delta_f \), as well as \( a_{k+1} = \text{push}(S(y_k)) \).

Let us take a closer look on the first part of the run: \( (y_0, a_1, \ldots, a_n, x_k) \) is equivalent to a run of \( \hat{P}_A \) that reaches a configuration \( x_k \). The latter is, following Proposition III, similar to a run of the original QDAS \( \mathcal{A} \) that reaches a configuration \( c = (G, d) \) where \( G \triangleright y_k \cdot S(y_k) \). Thus, \( c \in \text{Reach}(\mathcal{A}) \).

The transition \( (x_k, \text{push}(S(y_k)), x_{k+1}) \) now transfers the encoding of \( G \) to the stack, i.e., \( w_{k+1} = y_k \cdot S(y_k) \). All other information on data encoded in \( y_k \) is lost in this step.

Now, by Lemma I we know that the subrun \( (x_{k+1}, a_{k+2}, \ldots, a_n, x_n) \) leading to the final state of \( \mathcal{F}_f \) assures that \( |w_{k+1}|_s \geq f(s) \) for all \( s \in S \). Hence, for the previously found \( c = (G, d) \in \text{Reach}(\mathcal{A}) \) it holds that \( f \preceq \text{Parikh}(G) \). \( \square \)
B.2 Asynchronous Concurrent QDAS

Proposition 5 For all concurrent asynchronous QDAS \( A \) with set of location \( S \), we can build, in polynomial time, a PN \( N_A \) s.t. \( f \) is Parikh-coverable in \( A \) iff \( m \in \text{Cover}(N_A) \), where \( m \) is the marking s.t. for all \( s \in S \): \( m(s) = f(s) \) and for all \( p \in P \setminus S \): \( m(p) = 0 \).

The proof of the proposition relies on the following lemma, showing that \( N_A \) can simulate precisely the sequence of Parikh images that are reachable in \( A \). Let \((G,d)\) be a configuration of \( A \), and let \( m \) be marking of \( N_A \). We say that \( m \) encodes \((G,d)\), written \( m \models (G,d) \) iff: (i) for all \( x \in X \): \( m(x,d(x)) = 1 \), (ii) for all \( x \in X \): for all \( d \in D \setminus \{d(x)\}: m(x,d) = 0 \) and (iii) for all \( s \in S \): \( m(s) = \text{Parikh}(G)(s) \). Then:

Lemma 2 Let \( A \) be a concurrent asynchronous QDAS with set of variables \( X \) and set of locations \( S \), and let \( N_A \) be its associated PN. Then, for all \((G,d)\) \( \in \text{Reach}(A) \) there is \( m \in \text{Reach}(N_A) \) s.t. \( m \models (G,d) \) and for all \( m \in \text{Reach}(N_A) \), there is \((G,d) \in \text{Reach}(A) \) s.t. \( m \models (G,d) \).

Proof. We prove the two statements separately.

Let \((G,d)\) be a configuration in \( \text{Reach}(A_N) \), and let

\[
(G_0,d_0) a_0(G_1,d_1)a_1 \cdots a_{n-1} (G_n,d_n)
\]

be a run s.t. \((G,d) = (G_n,d_n)\). Let us build, inductively, a run \( m_0 m_1 \cdots m_k \) of \( N_A \) s.t. \( m_k \models (G,d) \). The induction is on the length \( n \) of the QDAS run.

Base case \( n = 0 \). It is easy to check that \( m_0 \models (G_0,d_0) \).

Inductive case \( n = \ell \). Let us assume that \( m_0 m_1 \cdots m_j \) is a run of \( N_A \) s.t. \( m_j \models (G_{\ell-1},d_{\ell-1}) \), and let us show how to complete it, if needed. We consider several cases depending on \( a_{\ell-1} \). In the case where \( a_{\ell-1} = \varepsilon \) and the scheduler action consists in dequeuing a block from a queue, we have \( \text{Parikh}(G_{\ell-1}) = \text{Parikh}(G_{\ell}) \) and \( d_\ell = d_{\ell-1} \). By induction hypothesis \( m_j \models (G_{\ell-1},d_{\ell-1}) \), hence \( m_j \models (G_{\ell},d_{\ell}) \), and we do not add elements to the run built so far. In the case where \( a_{\ell-1} = \text{dispatch}_\gamma(q, s') \) we assume \((s,s_{\ell-1},s') \in A \) is the corresponding LTS transition. Clearly, \( \text{Parikh}(G_{\ell})(s') = \text{Parikh}(G_{\ell-1})(s') + 1 \), \( \text{Parikh}(G_{\ell})(s) = \text{Parikh}(G_{\ell-1})(s) - 1 \), \( \text{Parikh}(G_{\ell})(s') = \text{Parikh}(G_{\ell-1})(s') + 1 \) and for all other location \( s \): \( \text{Parikh}(G_{\ell})(s) = \text{Parikh}(G_{\ell-1})(s) \). It is easy to check that the PN transition \( t \) s.t. \( I(t)(p) = 1 \) iff \( p = s \) and \( O(t)(p) = 1 \) iff \( p \in \{s', s''\} \) is fireable from \( m_j \) (as \( m_j \models (G_{\ell-1},d_{\ell-1}) \) by induction hypothesis) and yields the same effect, i.e. the marking \( m \) with \( m_j \models m \) is s.t. \( m \models (G_{\ell},d_{\ell}) \). All the other cases (test, assignment and task termination) are treated similarly.

Now, let \( m_0 m_1 \cdots m_n \) be a run of \( N_A \) and let us build, inductively, a run

\[
(G_0,d_0) a_0(G_1,d_1) a_1 \cdots a_{k-1} (G_k,d_k)
\]

s.t. \( m_n \models (G_k,d_k) \) and all the queues are empty in \( G_n \). The induction is on the length \( n \) of the PN run.

Base case \( n = 0 \). It is easy to check that \( m_0 \models (G_0,d_0) \).
Inductive case $n = t$. Let us assume that $(G_0, d_{0})a_0 \cdots a_{t-1}(G_j, d_j)$ is a run of $A$ s.t. $m_{t-1} \not\succ (G_j, d_j)$ and all the queues are empty in $G_j$. Let $t$ be the PN transition s.t. $m_{t-1} \xrightarrow{t} m_t$ and let us show how we can extend the run of $A$. We consider several cases. If $t$ is a transition that corresponds to an asynchronous dispatch, then there are $s, s', \gamma$ and $q$ s.t. $I_t(p) = 1$ iff $p = s$ and $O_t(p) = 1$ iff $p \in \{s', s_0\}$. By definition of $N_A$, there is a transition $(s, \text{dispatch}_A(\gamma, q), s')$ in $A$. Moreover, $m_{t-1}(s) \geq 1$, since $t$ is fireable from $m_{t-1}$. As $m_{t-1} \succ (G_j, d_j)$, the $(s, \text{dispatch}_A(\gamma, q), s')$ is fireable from $(G_j, d_j)$, and leads to a configuration $(G_{j+1}, d_{j+1})$, where a $\gamma$ block has been enqueued in $q$, hence $d_{j+1} = d_j$. Parikh$(G_{j+1})(s) = \text{Parikh}(G_j)(s) - 1$. By definition of $N_A$, there is a transition $(s', \text{dispatch}_A(\gamma, q), s')$ fireable from $(G_j, d_j)$, and leads to a configuration $(G_{j+1}, d_{j+1})$, where a $\gamma$ block has been enqueued in $q$, hence $d_{j+1} = d_j$. Parikh$(G_{j+1})(s) = \text{Parikh}(G_j)(s) - 1$, and for all other state $s''$: Parikh$(G_{j+1})(s'') = \text{Parikh}(G_j)(s'')$. It is easy to check that $m_t \succ (G_{j+1}, d_{j+1})$, however, queue $q$ contains a call to $\gamma$ in $G_{j+1}$ and is thus the only non-empty queue in this Cfg. Thus, from $(G_{j+1}, d_{j+1})$, we execute the scheduler action that dequeues from $q$. This has no effect on the Parikh image of the Cfg. Thus, we reach $(G_{j+2}, d_{j+2})$: $d_{j+1} = d_{j+2}$, Parikh$(G_{j+1}) = \text{Parikh}(G_{j+2})$, hence $m_t \succ (G_{j+2}, d_{j+2})$ too, and all the queues are empty in $G_{j+2}$, which concludes the induction step. All the other cases are treated similarly.

We can now prove Proposition 5.

Proof. It is easy to check that the construction of $N_A$, as described above, is polynomial. Then, assume $f$ is Parikh coverable in $A$, i.e. there is $(G, d) \in \text{Reach}(A)$ s.t. $f \preceq \text{Parikh}(G)$. By Lemma 2, there is $m' \in \text{Reach}(N_A)$ s.t. $m' \succ (G, d)$. Hence, for all $s \in S$: $m'(s) = \text{Parikh}(G)(s)$. Thus, for all $s \in S$: $m(s) = f(s) \leq \text{Parikh}(G)(s) = m'(s)$. Hence, $m \preceq m'$ (as $m(p) = 0$ for all $p \not\in S$). Since $m' \in \text{Reach}(N_A)$, we conclude that $m \in \text{Cover}(N_A)$. On the other hand, assume $m \in \text{Cover}(N_A)$, with $m(p) = 0$ for all $p \not\in S$, and let $f$ be s.t. for all $s \in S$: $f(s) = m(s)$. Since $m \in \text{Cover}(N_A)$, there is $m' \in \text{Reach}(N_A)$ s.t. $m \preceq m'$. By Lemma 2, there is $(G, d) \in \text{Reach}(A)$ s.t. $m' \succ (G, d)$. Hence, by definition of $\succ$, for all $s \in S$: $m'(s) = \text{Parikh}(G)(s)$. Thus, since $m \preceq m'$ and by definition of $f$, we conclude that for all $s \in S$: $f(s) = m(s) \leq m'(s) = \text{Parikh}(G)(s)$. Hence, $f$ is Parikh-coverable in $A$.

Proposition 6 For all PN $N$, we can build, in polynomial time, a concurrent asynchronous QDAS $A_N$ s.t. $m \in \text{Cover}(N)$ iff there exists $(G, d) \in \text{Reach}(A_N)$ with $G \succ m$.

The proof of Proposition 6 is split into two lemmata, given hereunder. They rely on an alternate characterization of $\text{Cover}(N)$. That is, $m \in \text{Cover}(N)$ iff $m$ is reachable by a so-called lossy run of $N$, i.e. a sequence of markings $m_0, m_1, \cdots, m_n$ s.t. $m_0 \preceq m_0$ and for all $0 \leq i \leq n - 1$: there is $\pi_{i+1}$ and a transition $t_i$ s.t. $m_i \xrightarrow{t_i} m_{i+1}$ and $m_i \preceq m_{i+1}$. Intuitively, a lossy run corresponds to firing a transition of the PN, and then spontaneously losing some tokens. The proof of these lemmata also assumes that each $p \in P$, the LTS $TS_p = \{(s_0^p, s_{mid}^p, s_{fin}^p), s_0^p, \Sigma, \Rightarrow\}$ is as depicted in Fig. 5.

Lemma 3 Let $N = (P, T, m_0)$ be a PN, and let $A_N = \langle CQID, \emptyset, \Gamma, \text{main}, \chi, \Sigma, (TS_p)_{p \in P} \rangle$ be its corresponding QDAS. If $m \in \text{Cover}(N)$ then there exists $(G, d) \in \text{Reach}(A_N)$ s.t. $G \succ m$. 

23
Proof. Let $m$ be a marking from $Cover(N)$. and let $m_0, m_1, \ldots, m_n$ be a lossy PN run s.t. $m = m_n$. The proof is by induction on the length of the run. More precisely, we show that, for all $0 \leq i \leq n$, there is a reachable configuration $(G_i, d_i) \in Reach(A_N)$ s.t.: for all $p \in P$: $d_i(v_p) = 0$, $G_i = \langle V^i, E^i, \lambda^i, queue^i, state^i \rangle$, $G_i \triangleright m$, $m \preceq m_i'$ and $E^i = \emptyset$.

**Base case:** $m_0$. Let us consider the run of $A_N$ that consists in: (a) executing block `main` up to line 8, then (b) emptying the queue $C$. The execution of (a) has the effect that: (i) all $v_p$ variables are initialized to 0 and keep this value, (ii) for all place $p$: at most $m_0(p)$ copies of block $p$ are asynchronously dispatched in queue $C$ and (iii) one copy of block `trans` is dispatched in $C$. Then, the execution of (b) creates one running task for each block that is present in $C$. Thus, the execution of (a) followed by (b) reaches a configuration $(G_0, d_0)$ with $G_0 = \langle V^0 = V_T^0 \cup V_C^0, E^0, \lambda^0, queue^0, state^0 \rangle$ s.t. $V_C^0 = \emptyset$ (the queue has been emptied), for all $p$: $|\{v \in V_T^0 | \lambda(v) = p\}| = m_0(p)$, $|\{v \in V_T^0 | \lambda(v) = \text{trans}\}| = 1$ and $E^0 = \emptyset$ (the queue is empty and all the calls are asynchronous). Moreover, `state` is such that each task running a $p$ block is still in its initial state $s_0^p$, hence $G_0 \triangleright m_0$. Similarly, the task running the `trans` block is about to enter the `while` loop at line 14. Finally, as the variables have been initialized to 0 and not modified, we have $d_0(v_p) = 0$ for all $p \in P$.

**Inductive case:** $m_i$. Let us assume there exist $(G_{i-1}, d_{i-1}) \in Reach(A_N)$ that respects all the conditions given at the beginning of the proof (in particular $G_{i-1} \triangleright m_{i-1}$). Let $t_i$ and $\overline{m}_i$ be the PN transition and marking s.t. $m_{i-1} \xrightarrow{t_i} \overline{m}_i$ and $m_i \preceq \overline{m}_i$ and let us show that $A_N$ can simulate it. This is achieved by the following sequence of actions in $A_N$. First, the block executing `trans` enters the `while` loop at line 14 and selects $t_i$ as transition $t$. Then, it sets all the variables $v_p$ s.t. $I_t(p) = 1$ to 1. Thus, at that point $v_p$ contains 1 iff $I_t(p) = 1$, since all $v_p$ variables were equal to 0 by induction hypothesis. Then, the task executing `trans` is blocked as it need to wait to the point were all $v_p$ are equal to 0. Since $G_{i-1} \triangleright m_{i-1}$ by induction hypothesis, we know that there are, in $G_{i-1}, m_{i-1}(p)$ tasks executing block $p$, for all $p \in P$. However, $t_i$ is fireable from $m_{i-1}$, and a loss of $\overline{m}_i - m_i$ tokens is still possible after the firing. Hence, $m_{i-1}(p) \geq (I_t(p) + \overline{m}_i(p) - m_i(p))$ for all $p$. Thus, for all $p$, there is at least $(I_t(p) + \overline{m}_i(p) - m_i(p))$ tasks executing $p$ in $G_{i-1}$. Thus, we complete the run of $A_N$ by letting, for all $p$, $(I_t(p) + \overline{m}_i(p) - m_i(p))$ task execute lines 11 in turn one after the other. Then, letting them all execute line 12, and reach their final state (Remark that all the $p$ task must first execute line 11 before one of them can execute line 12, as this sets $v_p$ to 0 and would prevent other tasks to execute line 11). This is possible because none of those tasks are blocked, since the CTG contains no edge, by induction hypothesis. At that point, $A_N$ has reached a configuration $(G', d')$ s.t. $d'(v_p) = 0$ for all $p \in P$ (by line 12) and where $G' \triangleright m_{i-1} - (I_t + \overline{m}_i - m_i)$. Moreover, $G'$ still respects all the other hypothesis as no new dispatch have been performed. Then, the simulation of $t_i$ proceeds by letting the `trans` task finish the current iteration of the main while
loop. This consists in executing the for loop of line 19, which dispatches one p block in C iff $O_t(p) = 1$, i.e., the effect of $t_i$ is to add a token to $p$. Finally, the scheduler empties queue $C$ and creates tasks for all the blocks that have just been added to $C$. It also kills all the p tasks that have reached their final state. As a consequence, the configuration that is reached is $(G_t, d_t)$, where $G_t \triangleright m_{t-1} - (t_{i_1} + \overline{m}_{t_1} - m_i) + O_{t_1} = (m_{t-1} - t_{i_1} + \overline{m}_{t_1} - m_i + m_i = \overline{m}_t - m_t + m_i = m_i$ and $d_t$ is s.t. $d_t(v_p) = 0$ for all $p \in P$. Moreover, since the queue has been emptied by the scheduler, $G_t$ contains only task nodes and no edge, as all the calls are asynchronous. The task executing trans is still active and at line 14, and all the p tasks are in their initial state.

Lemma 4 Let $N = \langle P, \Sigma, m_0 \rangle$ be a PN, and let $A_N = \langle CQID, \emptyset, \Gamma, \text{main}, \Sigma, (TS, \gamma)_{\gamma \in \Gamma} \rangle$ be its corresponding QDAS. If there are $(G, d) \in \text{Reach}(A_N)$ and $m$ s.t. $G \triangleright m \text{ then } m(G) \in \text{Cover}(N)$.

Proof. For a Ctg $G$ of $A_N$ with set of vertices $V$, we denote by $M(G)$ the marking of $N$ s.t. for all $p \in P$: $M(G)(p) = |\{v \in V | \text{state}(v) = s_p^i\}|$. Thus, in the case where $G$ encodes a configuration s.t. trans is at line 14, main is at line 8, and all the p blocks are in their initial state, then $G \triangleright M(G)$.

In order to establish the lemma, we prove a stronger statement: every time we reach, along a run, a configuration $(G, d)$ s.t. trans is at line 14, then $M(G) \in \text{Cover}(N)$. Formally, let $\rho = (G_0, d_0)\rho_0(G_1, d_1)\rho_1(G_2, d_2) \cdots (G_n, d_n)$ be a run of $A_N$, where, for all $0 \leq i \leq n: G_i = \langle V_i, E_i, \lambda_i, \gamma_i, \text{queue}_i, \text{state}_i \rangle$. Let $\pi : \{0, \ldots, k\} \rightarrow \{0, \ldots, n\}$ be the monotonically increasing function s.t. $k \leq n$ and for all $0 \leq j \leq n$: there exists $v \in V_j$ with $\text{state}_i(v) = s_{\text{trans}}^i$ if $0 \leq \ell \leq k$. That is the sequence $\pi(1), \pi(2), \ldots, \pi(k)$ identifies the indexes of all the configurations of the run where trans is at line 14. Let us show, by induction on $i$ that all the $M(G_{\pi(i)})$’s are reachable in the lossy semantics of $N$.

Base case $i = 0$. Let us show that $M(G_{\pi(0)}) = m_0$, i.e., that the first time trans reaches line 14, $M(G_{\pi(0)})$ is the initial marking of $N$. Observe that the prefix of the run must have the following form. Initially, only the main block is executing: it first sets all the variables $v_p$ to 0, then dispatches asynchronously at most $m_0(p)$ calls to each p block (for all $p \in P$), then finally dispatches an asynchronous call to trans and reaches line 8. Along this execution, the scheduler might decide to pick up some p blocks from $C$. However, as long as the scheduler has not scheduled the call to trans, the Ctg met along the run do not encode any marking, by definition of $\triangleright$. When the scheduler starts a task to run the trans block, we thus reach a configuration $(G, d)$ where: (i) the queue $C$ is empty, as dequeuing the trans block is possible only if all the p blocks have been dequeued, and no other dispatch has been performed; (ii) all the p tasks are blocked in their initial state as $d(t_p) = 0$ for all $p \in P$; and (iii) main is still blocked in the infinite loop at line 8. Since the scheduler has just dequeued trans from $C$, $G$ is necessarily the first Ctg to encode a marking, so $G = G_{\pi(0)}$. Moreover, by the loop at line 4, it is clear that $G \triangleright m$ with $m \leq m_0$.

Inductive case $i = \ell \geq 1$. The induction hypothesis is that $M(G_{\pi(\ell-1)}) \in \text{Cover}(N)$. Let us consider the $\rho' = (G_{\pi(\ell-1)}, d_{\pi(\ell-1)}) \cdots (G_{\pi(\ell)}, d_{\pi(\ell)})$, i.e., the portion of $\rho$ that allows to reach $(G_{\pi(\ell)}, d_{\pi(\ell)})$ from $(G_{\pi(\ell-1)}, d_{\pi(\ell-1)})$. We consider two cases:

1. Either trans has not performed an iteration of its main while loop along $\rho'$.
this case, the only actions that can occur along \( \rho' \) are scheduler actions consisting in dequeueing \( p \) blocks or the termination of some \( p \) tasks that were still in state \( s^p_{mid} \). In both cases, this does not modify the value of \( M(G) \), so \( M(G_{(n_i)}) = M(G_{(n_{i-1})}) \in \text{Cover}(N) \).

2. Or \( \text{trans} \) has performed a complete iteration of its main \( \text{while} \) loop possibly interleaved with the dequeue of \( p \) blocks and the termination of \( p \) tasks. Since the dequeues and terminations have no influence on the value of \( M(G) \) as argued above, let us focus on the effect of executing one iteration of the \( \text{while} \) loop. The iteration first selects a PN transition \( t \) and sets all the variables \( v_p \) s.t. \( I_i(p) = 1 \) to 1. The reached configuration is then \( (G, d) \) where \( M(G) = M(G_{(n_{i-1})}) \), as these operations do not manipulate \( p \) blocks or tasks. Then, \( \text{trans} \) is blocked by the test at line 18. As only \( p \) blocks can set \( v_p \) variables to 0, we are sure that, when \( \text{trans} \) reaches line 19, at least \( I_i(p) \) \( p \) blocks have left their initial state, for all \( p \in P \). Thus, when \( \text{trans} \) is at line 19, the configuration is \( (G', d') \), where for all \( p \in P \): \( M(G')(p) \leq M(G)(p) - I_i(p) = M(G_{(n_{i-1})}) - I_i(p) \). Afterwards, \( \text{trans} \) terminates the iteration of the \( \text{while} \) loop by dispatching \( O_t(p) \) \( p \) blocks for all \( p \in P \), and reaches line 14, which finishes \( \rho' \). Hence, we reach \( (G_{(n_i)}, d_{(n_i)}) \), where for all \( p \in P \): \( M(G_{(n_i)})(p) \leq M(G_{(n_{i-1})}) - I_i(p) + O_t(p) \). Since \( M(G_{(n_{i-1})}) \in \text{Cover}(N) \) by induction hypothesis, we conclude that \( M(G_{(n_i)}) \in \text{Cover}(N) \) too.

\[ \square \]

### B.3 Asynchronous Serial QDAS

The proof of Theorem 4 relies on the next Lemma, that formalizes the relationship between reachable configurations of \( A_F \) and reachable configurations of \( F \).

For all \( \gamma \in \Gamma \), we denote by \( s^\gamma \) the location of \( TS_\gamma \) that corresponds to line \( \ell \) in Fig. 5. Then, we say that a configuration \( (G, d) \) of \( A_F \) encodes a configuration \( (s, w) \) of \( F \), written \( (G, d) \triangleright (s, w) \) if: (i) \( s = d(\text{state}) \), (ii) \( G \) is of either shapes in Fig. 5 with \( w = m_1 \cdot \ldots \cdot m_n \), (iii) \( \text{Parikh}(G)(s^\text{main}) = 1 \) and (iv) there exists \( m \in M \cup \{ \varepsilon \} \) s.t. \( \text{Parikh}(G)(s^n_m) = 1 \). That is, \( s \) and \( w \) are encoded as described above, \( \text{main} \) is at line 8, and the running \( m \) block is at line 12. Then:

**Lemma 5** Let \( F \) be a FIFO system, let \( \gamma \) be a configuration of \( F \), and let \( A_F \) be its associated QDAS. For all run \( (s_0, w_0)(s_1, w_1) \cdots (s_n, w_n) \) of \( F \) s.t. for all \( 0 \leq i < n \): \( s_i \neq c \), there exists \( (G, d) \in \text{Reach}(A_F) \) s.t. \( (G, d) \triangleright (s_n, w_n) \). Moreover, for all \( (G, d) \in \text{Reach}(A_F) \) and for all configuration \( (s, w) \) of \( F \): \( (G, d) \triangleright (s, w) \) implies \( (s, w) \in \text{Reach}(F) \)

**Proof.** First, we consider a run \( (s_0, w_0)(s_1, w_1) \cdots (s_n, w_n) \) of \( F \) s.t. for all \( 0 \leq i < n \): \( s_i \neq c \), and build a run \( (G_0, d_0)(a_0(G_1, d_1) \cdots a_{k-1}(G_k, d_k)) \) of \( A_F \) s.t. \( (G_k, d_k) \triangleright (s_n, w_n) \), by induction on the length of \( F \)'s run.

**Base case** \( n = 0 \): Consider the run of \( A_F \) that consists in executing lines 5, 6, 7 of \( \text{main} \) (which sets the \( \text{head} \) variable to \( c \)), then dequeueing the \( c \) block from the queue, then executing lines 10 and 11 of \( c \). Remark that the test at line 10 is not satisfied, as \( \text{head} = c \), and that the queue is now empty. Clearly, the resulting configuration \( (G, d) \triangleright (s^0_F, w_0) \) as \( w_0 = c \).
Inductive case $n = \ell$. Let us assume that there is a reachable configuration $(G, d)$ of $A_F$ s.t. $(G, d) \triangleright (s_{t-1}, w_{t-1})$, and let us build a sequence of $A_F$ transitions that is fireable from $(G, d)$ and reaches a configuration encoding $(s_t, w_t)$. In $(G, d)$, there is, by definition of $\triangleright$, a task running a $b$ block, for $b \in M \cup \{\varepsilon\}$, that is at line 12. Moreover, $d(\text{state}) = s_{t-1}$. Let $\delta$ be the transition of $F$ s.t. $(s_{t-1}, w_{t-1}) \xrightarrow{\delta} (s_t, w_t)$. By hypothesis, $s_{t-1} \neq c$, hence we let $b$ execute line 12; select $\delta = (s_{t-1}, a, s_t)$ at line 13; execute line 14, where the condition of the if $\delta$ is not satisfied as $s = s_{t-1} = \text{state}$; and execute line 16, which reaches a configuration $(G', d')$ where $d'(\text{state}) = s_t$. We consider three cases to complete the simulation of $\delta$ in $A_F$. If $a = \varepsilon$, the $b$ task performs an asynchronous dispatch of $n$ to $q$, and jumps to line 11, then 12. Clearly, the resulting configuration $(G'', d'')$ is s.t. $(G'', d'') \triangleright (s_t, w_t)$ (in particular, the dispatch has correctly updated the content of the queue). If $a = \varepsilon$, the $b$ tasks jumps directly to line 11, then to line 12. Again, the resulting configuration $(G'', d'')$ is s.t. $(G'', d'') \triangleright (s_t, w_t)$, as the content of the queue has not been modified. Finally, if $a = \!\!=$, the running $b$ block sets $\text{head}$ to $n$ and terminates. Let $(G'', d'')$ be the $A_F$ configuration reached at that point. As $\delta$ is fireable from $(s_{t-1}, w_{t-1})$ in $F$, since $(G, d) \triangleright (s_{t-1}, w_{t-1})$, and as the content of the queue has not been modified since then, the $\text{head}$ of $q$ is necessarily an $n$ block in $G''$. Moreover, $d''(\text{head}) = n$ and $d''(\text{state}) = s_t$. Thus, we let the scheduler dequeue this $n$ block, and we let the task running it execute line 10 (where the condition of the if $\delta$ is not satisfied), then line 11. Clearly, the resulting configuration encodes $(s_t, w_t)$.

Now, let $\rho = (G_0, d_0) a_0(G_1, d_1) a_1 \cdots a_{n-1}(G_n, d_n)$ be a run of $A_F$ s.t. there is $(s, w)$ with $(G_n, d_n) \triangleright (s, w)$, and let us build, by induction on the length of this run, a run $(s_0^F, w_0)(s_1, w_1) \cdots (s_k, w_k)$ a run of $F$ s.t. $(s_k, w_k) = (s, w)$.

Let $K = \{\{(G_i, d_i) \mid \text{Parikh}(G_i)(s_i^F) = 1 \text{ for } m \in M \cup \{\varepsilon\}\}\}$, i.e., $K$ is the number of times an $m$ block reaches line 12 along $\rho$. Let us consider the increasing monotonic function $\rho : \{1, \ldots, K\} \rightarrow \{0, \ldots, n\}$ s.t. for all $0 \leq i \leq n$: there exists $m \in M \cup \{\varepsilon\}$ s.t. $\text{Parikh}(G_i)(s_i^F) = 1$ if and only if there is $1 \leq j \leq K$ s.t. $G_i = \rho(j)$, that is, $\rho(i)$ is the index, in $\rho$ of the $i$th time a configuration is reached where an $n$ block is at line 12. Clearly, by definition of $\triangleright$ only the $(G_{\rho(1)}, d_{\rho(1)})$ configurations (for $1 \leq j \leq K$) can encode a configuration of $F$, as no $n$ block is at line 12 in the other configurations of $\rho$. So, it is sufficient to show that all those $(G_{\rho(1)}, d_{\rho(1)})$ configurations encode a reachable configuration of $F$. We proceed by induction on $j$, and show that: for all $1 \leq j \leq K$: $(G_{\rho(j)}, d_{\rho(j)})$ encodes a reachable configuration of $F$ and $G_{\rho(j)}$ contains exactly one $m$ task (for $m \in M \cup \{\varepsilon\}$), that has been dequeued from $q$.

Base case $j = 0$: Observe that the subrun $(G_0, d_0) a_0 \cdots a_{\rho(1)-1}(G_{\rho(1)}, d_{\rho(1)})$ is necessarily an initialization phase where main sets state to $s_0^F$, head to $\varepsilon$, dispatches an $\varepsilon$ block, and reaches line 8, where it will stay forever. Then, the scheduler dequeues the $\varepsilon$ block, which empties the queue. The $\varepsilon$ task then traverses line 10 (as $\text{head} = \varepsilon$) and 11 and reaches line 12. So, clearly, $(G_{\rho(0)}, d_{\rho(0)}) \triangleright (s_0^F, \varepsilon)$ and contains exactly one $m$ task (for $m \in M \cup \{\varepsilon\}$), that has been dequeued from $q$.

Inductive case $j = \ell$: Let us assume that $(G_{\rho(\ell-1)}, d_{\rho(\ell-1)})$ encodes a reachable configuration $(s_{t-1}, w_{t-1})$ of $F$. We consider several cases. If $(G_{\rho(\ell-1)}, d_{\rho(\ell-1)}) = (G_{\rho(\ell)}, d_{\rho(\ell)})$ we are done. Otherwise, we have necessarily performed one iteration (possibly interrupted at line 12, 14 or 19) of the while loop starting at line 11, between
exist. Thus, we consider three cases:

- If we have entered the if at line 16 during the iteration, then a transition of the form \((s, !n, s')\) has been guessed, with state \(\text{state} = s\) and a dispatch of \(n\) has been performed into \(q\). As \((G_{\rho(t)}, d_{\rho(t)}) \triangleright (s_{\ell-1}, w_{\ell-1})\) by induction hypothesis, \(s_{\ell-1} = s\), and thus \((s, !n, s')\) is fireable from \((s_{\ell-1}, w_{\ell-1})\) and reaches \((s', n \cdot w_{\ell-1})\). Clearly, this configuration is encoded by \((G_{\rho(t)}, d_{\rho(t)})\).

- If we have entered the else if at line 17 during the iteration, then a transition of the form \((s, ?n, s')\) has been guessed, with state \(\text{state} = s\), head has been set to \(n\), the current \(m\) block has been terminated, a new block \(m'\) has been dequeued by the scheduler (as there is necessarily a running \(m\) block in \(G_{\rho(t)}\)). Moreover \(m' = n\), because \(m'\) has to be at line 12 in \(G_{\rho(t)}\), so the test of line 10 had to be false to allow \(m'\) to reach line 12. As \((G_{\rho(t)}, d_{\rho(t)}) \triangleright (s_{\ell-1}, w_{\ell-1})\) by induction hypothesis, \(s_{\ell-1} = s\). As a dequeue of a block \(m' = n\) has been performed, \(w_{\ell-1}\) is of the form \(w \cdot n\). Thus, \((s, ?m, s')\) is fireable from \((s_{\ell-1}, w_{\ell-1})\) and reaches \((s', w)\). Clearly, this configuration is encoded by \((G_{\rho(t)}, d_{\rho(t)})\).

- Finally, if neither the if nor the else if have been entered during the iteration, then a transition of the form \((s, \varepsilon, s')\) has been guessed, with state \(\text{state} = s\). As \((G_{\rho(t)}, d_{\rho(t)}) \triangleright (s_{\ell-1}, w_{\ell-1})\) by induction hypothesis, \(s_{\ell-1} = s\), and thus \((s, \varepsilon, s')\) is fireable from \((s_{\ell-1}, w_{\ell-1})\) and reaches \((s', w_{\ell-1})\). Clearly, this configuration is encoded by \((G_{\rho(t)}, d_{\rho(t)})\).

We can now prove Theorem 4.

**Proof.** Let \(F\) be a FIFO system, with set of messages \(M\) and associated serial asynchronous QDAS \(A_F\) and let \(c\) be a control location of \(F\). For all \(m \in M \cup \{\varepsilon\}\), let \(f_m\) be the Parikh image s.t. \(f_m(s_{21_{\text{main}}}) = 1\) and \(f_m(s) = 0\) for all \(s \neq s_{21_{\text{main}}}\). Remark that there are only finitely many such \(f_m\). Then, we show that \(c\) is reachable in \(F\) if and only if there exists \(m \in M \cup \{\varepsilon\}\) s.t. \(f_m\) is Parikh-coverable in \(A_F\).

Assume \(c\) is reachable in \(F\), and let \((c, w)\) be a configuration in \(Reach(F)\). Without loss of generality, assume \(c\) is reachable by run that visits \(c\) only once. By Lemma 5 there is \((G, d) \in Reach(A_F)\) s.t. \((G, d) \triangleright (c, w)\). Hence, in \((G, d)\), there is a task running an \(m\) block (for \(m \in M \cup \{\varepsilon\}\)) that is at line 12, and \(d(\text{state}) = c\). Thus, \(m\) can execute one step and reach line 21, so \(f_m\) is Parikh-coverable in \(A_F\).

For the reverse direction, assume there is \(m \in M \cup \{\varepsilon\}\) that is Parikh-coverable in \(A_F\). Hence, there is \((G, d) \in Reach(A_F)\) where a task running block \(m\) is at line 21. The only way for that block to reach line 21 is from line 12, with a valuation \(d'\) s.t. \(d'(\text{state}) = c\). Thus, there is, in \(Reach(A_F)\) a configuration \((G', d')\) with \(d'(\text{state}) = c\), a task running an \(m\) block at line 12, and necessarily \(\text{main}\) at line 8 (otherwise, only \(\text{main}\) would be running). Hence, \((G', d')\) is a reachable configuration
of $A_F$ s.t. $(G', d') \triangleright (c, w)$ for some queue content $w$. Thus, by Lemma 5, $(c, w) \in \text{Reach}(F)$, and $c$ is reachable in $F$.

We have thus reduced the control location reachability problem of FIFO systems to the Parikh coverability problem of serial asynchronous QDAS (using only one serial queue). The former is undecidable. Hence the theorem. □
